

## Automatic Command Queue Scheduling for Task-Parallel Workloads in OpenCL

Ashwin M. Aji,<sup>\*</sup> Antonio J. Peña,<sup>‡</sup> Pavan Balaji,<sup>‡</sup> Wu-chun Feng,<sup>†</sup><sup>\*</sup>AMD Research, Advanced Micro Devices, Inc. [ashwin.aji@amd.com](mailto:ashwin.aji@amd.com)<sup>†</sup>Department of Computer Science, Virginia Tech. [feng@cs.vt.edu](mailto:feng@cs.vt.edu)<sup>‡</sup>Math. and Comp. Sci. Division, Argonne National Laboratory {[apenya](mailto:apenya@mcs.anl.gov), [balaji](mailto:balaji@mcs.anl.gov)}**Abstract—**

OpenCL is a portable interface that can be used to program cluster nodes with heterogeneous compute devices. The OpenCL specification tightly binds its workflow abstraction, or “command queue,” to a specific device for the entire program. For best performance, the user has to find the ideal queue–device mapping at command queue *creation time*, an effort that requires a thorough understanding of the match between the characteristics of all the underlying device architectures and the kernels in the program. In this paper, we propose to add scheduling attributes to the OpenCL context and command queue objects that can be leveraged by an intelligent runtime scheduler to automatically perform ideal queue–device mapping. Our proposed extensions enable the average OpenCL programmer to focus on the algorithm design rather than scheduling and automatically gain performance without sacrificing programmability.

As an example, we design and implement an OpenCL runtime for task-parallel workloads, called MultiCL, which efficiently schedules command queues across devices. Within MultiCL, we implement several key optimizations to reduce runtime overhead. Our case studies include the SNU-NPB OpenCL benchmark suite and a real-world seismology simulation. We show that, on average, users have to apply our proposed scheduler extensions to only *four* source lines of code in existing OpenCL applications in order to automatically benefit from our runtime optimizations. We also show that MultiCL always maps command queues to the optimal device set with negligible runtime overhead.

## I. INTRODUCTION

Coprocessors are being increasingly adopted in today’s high-performance computing (HPC) clusters. In particular, production codes for many scientific applications, including computational fluid dynamics, cosmology, and data analytics, use accelerators for high performance and power efficiency. Diverse types of accelerators exist, including graphics processing units (GPUs) from NVIDIA and AMD and the Xeon Phi coprocessor from Intel. Compute nodes typically include CPUs and a few accelerator devices. In order to enable programmers to develop portable code across coprocessors from various vendors and architecture families, general-purpose parallel programming models, such as the Open Computing Language (OpenCL) [1], have been developed and adopted.

OpenCL features workflow abstractions called *command queues* through which users submit read, write and execute commands to a specific device. However, the OpenCL specification tightly couples a command queue with a specific single device for the entire execution with no runtime support for cross-device scheduling. For best performance, programmers

thus have to find the ideal mapping of a queue to a device at command queue *creation time*, an effort that requires a thorough understanding of the kernel characteristics, the underlying device architecture, node topology, and various data-sharing costs that can severely hinder programmability. Researchers have explored splitting data-parallel kernels across multiple OpenCL devices, but their approaches do not work well for scheduling task-parallel workloads with multiple concurrent kernels across several command queues.

To automatically gain performance in OpenCL programs without sacrificing programmability, we decouple the command queues from the devices by proposing scheduling policies to the OpenCL specification. We define new attributes to the `cl_context` and `cl_command_queue` objects, which denote global and local scheduling policies, respectively. While the context-specific global scheduling policy describes the queue–device mapping methodology, the queue-specific local policy indicates individual queue scheduling choices and workload hints to the runtime. Local queue scheduling policies may be applied for the entire lifetime of the command queues, implicit synchronization epochs, or any explicit code regions. We also propose a new OpenCL API to specify per-device kernel execution configurations; this function enables the scheduler to dynamically choose the appropriate configuration at kernel launch time, thereby associating a kernel launch with a high-level command queue rather than the actual physical device. Our proposed hierarchical scheduling policies enable the average user to focus on enabling task parallelism in algorithms rather than device scheduling.

To demonstrate the efficacy of our proposed OpenCL extensions, we design and implement MultiCL, an example runtime system for task-parallel workloads that leverages the policies to dynamically schedule queues to devices. We build MultiCL on top of the SnuCL OpenCL implementation [2], which provides cross-vendor support. We design three runtime modules in MultiCL: an offline device profiler, an online kernel profiler, and an online device mapper. We also implement several optimizations to reduce the online kernel profiling overhead, including efficient device–to–device data movement for data-intensive kernels, minikernel profiling for compute-intensive kernels, and caching of profiled data parameters.

Our proposed API extensions are OpenCL version independent. By providing simple modular extensions to the familiar OpenCL API, we enable different schedulers to be composed and built into an OpenCL runtime. We do not aim to design the hypothetical one–size–fits–all ideal scheduling algorithm. Instead, users may choose the right set of runtime parameters

This work was done when Ashwin was a Ph.D. student at Virginia Tech.

to control scheduling decisions depending on the program’s requirements and the user’s programming skill level. Our solution thus enhances programmability and delivers automatic performance gains.

Our case studies include the SNU-NPB OpenCL benchmark suite and a real-world seismology simulation. We show that, on average, users have to modify only *four* source lines of code in existing applications in order to benefit from our runtime optimizations. Our MultiCL runtime always schedules command queues to the optimal device combination, with an average runtime overhead of 10% for the SNU-NPB benchmarks and negligible overhead for the seismology simulation.

The paper is organized as follows. In Section II we describe relevant details of the OpenCL programming model, and in Section III we discuss some related work. In Section IV, we describe our proposed OpenCL extensions. The MultiCL runtime design and optimizations are discussed in Section V, and an experimental evaluation is presented in Section VI. We present concluding thoughts in Section VII.

## II. BACKGROUND

In this section, we review the OpenCL programming model and describe the SnuCL framework and runtime system, which we extend in this work.

### A. OpenCL Programming Model

OpenCL [1] is an open standard and parallel programming model for a variety of platforms, including NVIDIA and AMD GPUs, FPGAs, Intel Xeon Phi coprocessors, and conventional multicore CPUs, in which the different devices are exposed as accelerator coprocessors. OpenCL follows a kernel-offload model, where the data-parallel, compute-intensive portions of the application are offloaded from the CPU host to the coprocessor device.

OpenCL developers must pick one of the available platforms or OpenCL vendor implementations on the machine and create *contexts* within which to run the device code. Data can be shared only across devices within the same context. A device from one vendor will not typically be part of the same platform and context as the device from another vendor.

While OpenCL is a convenient programming model for writing portable applications across multiple accelerators, its performance portability remains a well-known and open issue [3]. Application developers may thus maintain different optimizations of the same kernel for different architectures and explicitly query and schedule the kernels to be executed on the specific devices that may be available for execution.

In OpenCL, kernel objects are created per context. However, the kernel launch configuration or work dimensions are set globally per kernel object at kernel launch, and per-device kernel configuration customization is possible only through custom conditional programming at the application level. No convenient mechanism exists, however, to set different kernel configurations for different kernel-device combinations dynamically. Therefore, the OpenCL interface and device scheduling are tightly coupled.

### B. SnuCL

SnuCL [2] is an open source OpenCL implementation and runtime system that supports cross-vendor execution and data sharing in OpenCL kernels. This OpenCL implementation provides users with a unified OpenCL platform on top of the multiple separate vendor-installable client drivers. SnuCL features an optional cluster mode providing seamless access to remote accelerators using MPI for internode communications.

In our work we extend SnuCL’s single-node runtime mode for cross-vendor execution. Although our optimizations can be applied directly to the cluster mode as well, these fall out of the scope of this paper.

## III. RELATED WORK

The problem of scheduling among CPU and GPU cores has been extensively studied and falls broadly into two categories: interapplication scheduling and intra-application scheduling.

### A. Interapplication Scheduling

Interapplication schedulers [4], [5] distribute entire kernels from different applications across the available compute resources. Their solutions are designed primarily for multitenancy, power efficiency, and fault tolerance in data centers.

Remote accelerator virtualization solutions such as the cluster mode of SnuCL, rCUDA [6], [7], or VOCL [8] provide seamless access to accelerators placed on remote nodes. These address the workload distribution concern in different ways. SnuCL’s cluster mode permits remote accelerator access in clusters only to those nodes within the task allocation, and users have to implement their own workload distribution and scheduling mechanisms. rCUDA enables global pools of GPUs within compute clusters, performing cross-application GPU scheduling by means of extensions to the cluster job scheduler [9]; as with SnuCL, users have to explicitly deal with load distribution and scheduling within the application. VOCL implements its own automatic scheduler, which can perform device migrations according to energy, fault tolerance, on-demand system maintenance, resource management, and load-balancing purposes [10], [11]. This scheduling mechanism, however, is limited to performing transparent context migrations among different accelerators; it is not aimed at providing performance-oriented workload distribution and scheduling.

While some of these solutions provide scheduling support across applications, our solution provides scheduling capabilities across command queues *within* an application.

### B. Intra-application Scheduling

Intra-application scheduling strategies are programming model dependent. These distribute either loop iterations in directive-based applications or work groups in explicit kernel offload-based models; in other words, *work* can mean either loop iterations or work groups. These are essentially *device aggregation* solutions, where the scheduler tries to bring homogeneity to the heterogeneous cores by giving them work proportional to their compute power.

The possibility of presenting multiple devices as a single device to the OpenCL layer and performing workload distribution internally has been previously explored. Both [12] and [13] use static load-partitioning approaches for intrakernel workload distribution, and the authors of [12] leverage their own API. FluidiCL [14] performs work stealing to dynamically distribute work groups among CPU and GPU cores with low overhead. Maestro [15] is another unifying solution addressing device heterogeneity, featuring automatic data pipelining and workload balancing based on a performance model obtained from install-time benchmarking. Maestro’s approach requires autotunable kernels that obtain the size of their workloads at runtime as parameters. Qilin [16] does adaptive mapping of computation to CPU and GPU processors by using curve fitting against an evolving kernel performance database. These approaches provide fine-grained scheduling at the kernel or loop level and exploit data parallelism in applications. In contrast, our work performs coarser-grained scheduling at the *command queue* level to enable task parallelism between kernels and command queues in applications.

SOCL [17] also extends OpenCL to enable automatic task dependency resolution and scheduling, and performs automatic device selection functionality by performance modeling. It applies the performance modeling at kernel granularity, and this option is not flexible. In contrast, we perform workload profiling at synchronization epoch granularity. Our approach enables a more coarse-grained and flexible scheduling that allows making device choices for kernel groups rather than individual kernels. Also, our approach reduces the profile lookup time for aggregate kernel invocations, decreasing runtime overhead. In SOCL, dynamically scheduled queues are automatically distributed among devices, being bound for the entire duration of the program. In our work, conversely, we enable users to dynamically control the duration of queue–device binding for specific code regions for further optimization purposes. In addition, we enable scheduling policies at both the context level (*global*) and the command queue level (*local*). The latter may be set and reset during different phases of the program. Furthermore, our solution enables the launch configuration to be decoupled from the launch function, providing kernel–device configuration customization capabilities.

#### IV. PROPOSED OPENCL EXTENSIONS

In this section we describe our proposed OpenCL API extensions (Table I) to express global and local scheduling policies and decouple kernel launches from the actual device.

##### A. Contextwide Global Scheduling

To express global queue scheduling mechanisms, we propose a new context property called `CL_CONTEXT_SCHEDULER`. This context property can be assigned to a parameter denoting the global scheduling policy. Currently, we support two global scheduler policies: *round robin* and *autofit*. The round-robin policy schedules the command queue to the next available device when the

TABLE I: Proposed OpenCL Extensions

CL Function	CL Extensions	Parameter Names	Options
<code>clCreateContext</code>	New parameters and options	<code>CL_CONTEXT_SCHEDULER</code>	<code>ROUND_ROBIN</code> <code>AUTO_FIT</code>
<code>clCreateCommandQueue</code>	New parameters	<code>SCHED_OFF</code> <code>SCHED_AUTO_STATIC</code> <code>SCHED_AUTO_DYNAMIC</code> <code>SCHED_KERNEL_EPOCH</code> <code>SCHED_EXPLICIT_REGION</code> <code>SCHED_ITERATIVE</code>	N/A
<code>clSetCommandQueueSchedProperty</code>	New CL API	<code>SCHED_COMPUTE_BOUND</code> <code>SCHED_IO_BOUND</code> <code>SCHED_MEMORY_BOUND</code>	
<code>clSetKernelWorkGroupInfo</code>	New CL API	N/A	N/A

scheduler is triggered. This approach is expected to cause the least overhead but not always produce the optimal queue–device map. On the other hand, the autofit policy decides the most optimal queue–device mapping when the scheduler is triggered. The global policies, in conjunction with the local command queue specific options, will determine the final queue–device mapping.

##### B. Local Scheduling Options

While command queues that are created within the same context share data and kernel objects, they also share the context’s global scheduling policy. We extend the OpenCL command queue to specify a local scheduling option that is queue-specific. The combination of global and local scheduler policies can be leveraged by the runtime to result in a more optimal device mapping. The command queue properties are implemented as bitfields, and so the user can specify a combination of local policies.

Setting the command queue scheduling property to either `SCHED_AUTO_*` or `SCHED_OFF` determines whether the particular queue is opting in or out of the automatic scheduling, respectively. For example, an intermediate or advanced user may want to manually optimize the scheduling of just a subset of the available queues by applying the `SCHED_OFF` flag to them, while the remaining queues may use the `SCHED_AUTO_DYNAMIC` flag to participate in automatic scheduling. Static vs. dynamic automatic scheduling provides a tradeoff between speed and optimality, which is explained in Section V. Command queue properties can also specify scheduler triggers to control the scheduling frequency and scheduling code regions. For example, the `SCHED_KERNEL_EPOCH` flag denotes that scheduling should be triggered after a batch of kernels (*kernel epoch*) is synchronized and not after individual kernels. The `SCHED_EXPLICIT_REGION` flag denotes that scheduling for the given queue is triggered between explicit start and end regions in the program, and the new `clSetCommandQueueSchedProperty` OpenCL command is used to mark the scheduler region and set more scheduler flags if needed. Queue properties may also be used to provide optimization hints to the scheduler. Depending on the expected type of computation in the given queue, the following properties may be used: `SCHED_COMPUTE_BOUND`, `SCHED_MEM_BOUND`, `SCHED_IO_BOUND`, or `SCHED_ITERATIVE`. For example, if the `SCHED_COMPUTE_BOUND` flag is used, the runtime

chooses to perform minikernel profiling to reduce overhead (see Section V).

The proposed command queue properties are meant to be used as fine-tuning parameters for scheduling; their use by all programmers is not mandatory. Advanced users may choose to ignore all the properties completely and instead manually schedule all the queues, whereas intermediate users may have some knowledge of the program and may select a subset of properties as runtime hints (e.g., `SCHED_COMPUTE_BOUND` or `SCHED_IO_BOUND`) depending on the workload type. Nonexperienced users may just use `SCHED_AUTO_DYNAMIC` and ignore the rest of the properties, so that the runtime decides everything for them, at the expense of a potentially higher runtime overhead and lower performance.

### C. Device-Specific Kernel Configuration

The parameters to the OpenCL kernel launch functions include a command queue, a kernel object, and the kernel's launch configuration. The launch configuration is often determined by the target device type, and it depends on the device architecture. Currently, per-device kernel configuration customization is possible only through custom conditional programming at the application level. The device-specific launch function forces the programmer to manually schedule kernels on a device, which leads to poor programmability.

We propose a new OpenCL API function called `clSetKernelWorkGroupInfo` to independently set unique kernel configurations to different devices. The purpose of this function is to enable the programmer to separately express the different combinations of kernel configuration and devices beforehand so that when the runtime scheduler maps the command queues to the devices, it can also profile the kernels using the device-specific configuration that was set before. The `clSetKernelWorkGroupInfo` function may be invoked at any time before the actual kernel launch. If the launch configuration is already set before the launch for each device, the runtime simply uses the device-specific launch configuration to run the kernel on the dynamically chosen device. We do not change the parameters to the `clEnqueueNDRangeKernel` nor any other launch API, but the kernel configuration parameters are ignored if they are already set by using `clSetKernelWorkGroupInfo`.

### D. Discussion on Compatibility

The function `clCreateSubDevices` from OpenCL 1.2 creates a group of `cl_device_id` subobjects from a parent device object. Our solution works seamlessly with `cl_device_id` objects that are returned either by the OpenCL platform or by the `cl_device_id` objects that are created by `clCreateSubDevices`. Our example scheduler handles all `cl_device_id` objects and makes queue-device mapping decisions uniformly.

Since our solution involves the most basic OpenCL objects (e.g., contexts, command queues, and kernels), our work is compatible with all OpenCL versions (1.0, 1.1, 1.2, and 2.0). Our work does not rely on characteristics of particular OpenCL

versions, thus making it a generic and forward-compatible solution. New OpenCL 2.0 features, such as on-device queues, are worthy of separate studies and left for future work.

## V. THE MULTICL RUNTIME SYSTEM

In this section, we explain the design of the MultiCL runtime system and discuss key optimization tradeoffs.

### A. Design

The SnuCL runtime creates a *scheduler* thread per user process, but the default scheduler thread statically maps the incoming commands to the explicitly chosen target device—that is, manual scheduling. MultiCL is our extension of the SnuCL runtime, with the added functionality of automatic command queue scheduling support to OpenCL programs. MultiCL's design is depicted in the left portion of Figure 1. The user's command queues that are created with the `SCHED_OFF` flag will be statically mapped to the chosen device, whereas those that have the `SCHED_AUTO` flag are automatically scheduled by MultiCL. Further, the user-specified context property (e.g., `AUTO_FIT`) determines the scheduling algorithm for the pool of dynamically mapped command queues. Once a user queue is mapped to the device, its commands are issued to the respective device-specific queue for final execution.

The MultiCL runtime consists of three modules: (1) device profiler, where the execution capabilities (memory, compute, and I/O) of the participating devices are collected or inferred; (2) kernel profiler, where kernels are transformed and their execution times on different devices are measured or projected; and (3) device mapper, where the participating command queues are scheduled to devices so that queue completion times are minimal. The OpenCL functions that trigger the respective modules are shown in the right portion of Figure 1.

*Device Profiler:* The device profiler, which is invoked once during the `clGetPlatformIds` call, retrieves the static device profile from the profile cache. If the profile cache does not exist, then the runtime runs data bandwidth and instruction throughput benchmarks and caches the measured metrics as static per-device profiles in the user's file system. The profile cache location can be controlled by environment variables. The benchmarks are derived from the SHOC benchmark suite [18] and NVIDIA SDK and are run for data sizes ranging from being latency bound to bandwidth bound. Benchmarks measuring host-to-device (H2D) bandwidths are run for all the CPU socket-device combinations, whereas the device-to-device (D2D) bandwidth benchmarks are run for all device-device combinations. These benchmarks are included as part of the MultiCL runtime. Bandwidth numbers for unknown data sizes are computed by using simple interpolation techniques. The instruction throughput of a device (or peak flop rate) can also be obtained from hardware specifications and manually included in the device profile cache. The benchmarks are run again only if the system configuration changes, for example, if devices are added or removed from the system or the device profile cache location changes. In practice, however, the

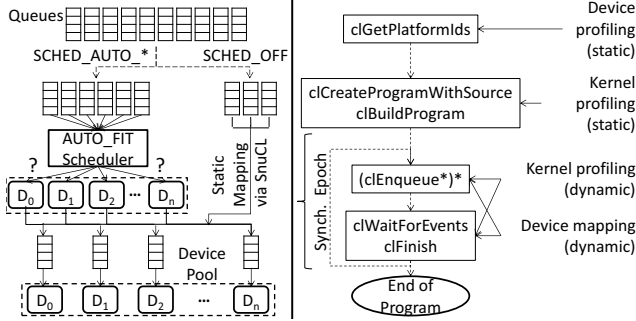

Fig. 1: Left: MultiCL runtime design and extensions to SnucL. Right: Invoking MultiCL runtime modules in OpenCL programs.

runtime just reads the device profiles from the profile cache once at the beginning of the program.

*Kernel Profiler:* Kernel execution times can be estimated by performance modeling or performance projection techniques, but these approaches either are done offline or are impractical because of their large runtime overheads. We follow a more practical approach in that we run the kernels once per device and store the corresponding execution times as part of the kernel profile. Arguably, this approach may cause potential runtime overhead to the current programs; in this section we therefore discuss several ways to mitigate the overhead. Our experiments (Section VI) indicate that, upon applying the runtime optimizations, the runtime overhead is minimal or sometimes negligible while the optimal device combinations are chosen for the given kernels. Static kernel transformations, such as minikernel creation, are performed during `clCreateProgramWithSource` and `clBuildProgram`, whereas dynamic kernel profiling is done at synchronization points or at user-defined code regions.

*Device Mapper:* Each `clEnqueue`-command is intercepted by the device mapper, and the associated queue is added to a ready queue pool for scheduling. We use the per-queue aggregate kernel profiles and apply a simple dynamic programming approach to determine the ideal queue-device mapping that minimizes the concurrent execution time. The dynamic programming approach guarantees ideal queue-device mapping and, at the same time, incurs negligible overhead because the number of devices in present-day nodes is not high. Once the scheduler is invoked and maps the queue to a device, the queue is removed from the queue pool, and its commands are issued to the new target device. On the one hand, the scheduler can *actively* be invoked for every kernel invocation, but that approach can cause significant runtime overhead due to potential cross-device data migration. On the other hand, the runtime can simply aggregate the profiled execution costs for every enqueue command, and the scheduler can be invoked at synchronization epoch boundaries or at any other user-specified location in the program. The scheduler options discussed in the previous section can be used to control the frequency and location of invoking the scheduler, which can further control the overhead vs. optimality tradeoff.

## B. Static Command Queue Scheduling

Users can control which command queues participate in static queue scheduling (`SCHED_AUTO_STATIC`) and which of them are scheduled dynamically (`SCHED_AUTO_DYNAMIC`). In the static command queue scheduling approach, we use the device profiler and device mapper modules of our runtime and do not perform dynamic kernel profiling; in other words, we statically decide the command queue schedules based only on the device profiles. Users can select this mode as an approximation to reduce scheduling overhead, but the optimal device may not be selected certain times. The MultiCL runtime uses the command queue properties (compute intensive, memory intensive, or I/O intensive) as the selection criterion and chooses the best available device for the given command queue.

## C. Dynamic Command Queue Scheduling

In the dynamic command queue scheduling approach, we use the kernel profiling and device mapping modules of our runtime and selectively use the device profiling data. That is, we dynamically decide the command queue schedules based only on the kernel and device profiles. Users can choose runtime options to mitigate the runtime overhead associated with dynamic kernel profiling.

1) *Kernel Profile Caching for Iterative Kernels:* We cache the kernel profiles in memory as key-value pairs, where the key is the kernel name and the value is its performance vector on the devices. The cached kernel profiles are used to schedule future kernel invocations. We define a *kernel epoch* as a collection of kernels that have been asynchronously enqueued to a command queue. Synchronizing after a kernel epoch on the command queue will block until all the kernels in the epoch have completed execution. We also cache the performance profiles of kernel epochs for further overhead reduction. The key for a kernel epoch is just the set of the participating kernel names, and the value is the aggregate performance vector of the epoch on all the devices. The user can provide runtime options to batch schedule either kernel epochs or individual kernels. Our approach significantly reduces kernel profiling overhead.

Iterative kernels benefit the most because of kernel reuse. Arguably, some kernels may perform differently across iterations, however, or their performances may change periodically depending on the specific phase in the program. To address this situation, the user can set a program environment flag to denote the iterative scheduler frequency, which tells our scheduler when to recompute the kernel profiles and rebuild the profile cache. In practice, we have found iterative kernels to have the least overhead, because the overhead that is incurred during the first iteration or a subset of iterations is amortized over the remaining iterations.

2) *Minikernel Profiling for Compute-Intensive Kernels:* While kernel profile caching helps iterative applications, non-iterative applications still incur profiling overhead, a situation that is especially true for compute-intensive kernels. To select

```

1  __kernel void foo(...) {
2  /* MultiCL inserts the below transformation code
3   to run only the first workgroup (minikernel) */
4  if(get_group_id(0)+get_group_id(1)+get_group_id(2)!=0)
5  return;
6  /* ... actual kernel code ... */
7  }

```

Fig. 2: Minikernel transformation example.

the best device, we need to know only the kernel’s *relative* performances and not necessarily the absolute kernel performances. Therefore, we create a technique called *minikernel profiling*, which is conceptually similar to our miniemulation technique [19], where we run just a single workgroup of the kernel on each participating device and collect the relative performances in the kernel profiles. Our approach dramatically reduces runtime overhead, as discussed in Section VI. The minikernel profiling approach is best suited for those kernels whose workgroups often exhibit similar behavior and share similar runtime statistics, a situation typical of data-parallel workloads. Minikernel profiling is enabled by using the `SCHED_COMPUTE_BOUND` flag. However, users who want more profiling accuracy for the given workload can simply ignore the flag to enable full kernel profiling, but with some runtime overhead.

To implement minikernel profiling, we cannot simply launch a kernel with a single workgroup, because the kernel’s work distribution logic may not guarantee a reduction in the profiling overhead. Instead, we modify the source kernel to create a *minikernel*, and we insert a conditional that allows just the first workgroup to execute the kernel and force all the other workgroups to return immediately (e.g., Figure 2). We profile the minikernel with the same launch configuration as the original kernel, so the kernel’s work distribution does not change the amount of work done by the first workgroup. Our approach thus guarantees reduction in the profiling overhead.

We intercept the `clCreateProgramWithSource` call and create a minikernel object for every kernel. We build the program with the new minikernels into a separate binary by intercepting the `clBuildProgram` call. While this method doubles the OpenCL build time, we consider this to be an initial setup cost that does not change the actual runtime of the program. We note also that the minikernel profiling approach requires access to the kernel source in order to perform the optimization.

3) *Data Caching for I/O-Intensive Kernels*: One of the steps in kernel profiling is to transfer the input data sets from the source device to each participating device before profiling them. Clearly, the data transfer cost adds to the runtime overhead. With  $n$  devices, the brute-force approach involves making D2D data transfers  $n - 1$  times from the source device to every other device, followed by an intradevice data transfer at the source. However, the current vendor drivers do not support direct D2D transfer capabilities across vendors and device types. Thus, each D2D transfer is performed as a D2H-H2D double operation via the host memory, which means

that there will be  $n - 1$  D2H and  $n - 1$  H2D operations.<sup>1</sup> Recognizing, however, that the host memory is shared among all the devices within a node, we optimize the data transfer step by doing just a single D2H copy from the source device to the host, followed by  $n - 1$  H2D data transfers. In addition, we cache the incoming data sets in each destination device so that if our device mapper decides to migrate the kernel to a different target device, the required data is already present in the device. With this optimization, however, we trade off increased memory footprint in each device for less data-transfer overhead.

## VI. EVALUATION

We describe the experimental setup and demonstrate the efficacy of our runtime optimizations using a benchmark suite and a real-world seismology simulation application.

### A. Experimental Setup

Our experimental compute node has a dual-socket octo-core AMD Opteron 6134 (Magny-Cours family) processor and two NVIDIA Tesla C2050 GPUs, thus forming three OpenCL devices (1 CPU and 2 GPU devices). Each CPU node has 32 GB of main memory, and each GPU has 3 GB of device memory. We use the CUDA driver v313.30 to manage the NVIDIA GPUs and the AMD APP SDK v2.8 to drive the AMD CPU OpenCL device. The network interface is close to CPU socket 0, and the two NVIDIA GPUs have affinity to socket 1, which creates nonuniform host–device and device–device distances (and therefore data transfer latencies) depending on the core affinity of the host thread. The MultiCL runtime scheduler incorporates the heterogeneity in compute capabilities as well as device distances when making device mapping decisions.

### B. Applications and Results

We first present our evaluation of the NAS Parallel Benchmarks. We then discuss the results we obtained for the seismology application.

1) *NPB*: The NAS Parallel Benchmarks (NPB) [20] are designed to help evaluate current and future parallel supercomputers. The SnuCL team recently developed the SNU-NPB suite [21], which consists of the NPB benchmarks ported to OpenCL. The SNU-NPB suite also has a multidevice version of the OpenCL code (SNU-NPB-MD) to evaluate OpenCL’s scalability. SNU-NPB-MD consists of six applications: BT, CG, EP, FT, MG, and SP. The OpenCL code is derived from the MPI Fortran code that is available in the “NPB3.3-MPI” suite and is not heavily optimized for the GPU architecture. For example, Figure 3 shows that for the single-device version, most of the benchmarks run better on the CPU but the degree of speedup varies, whereas EP runs faster on the GPU. These results mean that the device with the highest theoretical peak performance and bandwidth—that is, the GPU—is not always the best choice for a given kernel.

<sup>1</sup>GPUDirect for NVIDIA GPUs has markedly limited OpenCL support.

Each SNU-NPB-MD benchmark has specific restrictions on the number of command queues that can be used depending on its data and task decomposition strategies, as documented in Table II. Also, the amount of work assigned per command queue differs per benchmark. That is, some create constant work per application, and the work per command queue decreases for more queues; others create constant work per command queue, and the work per application increases for more queues. To use more command queues than the available devices in the program, one could write a simple round-robin queue–device scheduler, but an in-depth understanding of the device architecture and node topology is needed for ideal scheduling. Also, some kernels have different device-specific launch configuration requirements depending on the resource limits of the target devices; and, by default, these configurations are specified only at kernel launch time. Moreover, such kernels are conditionally launched with different configurations depending on the device type (CPU or GPU). In order to *dynamically* choose the ideal kernel–device mapping, a scheduler will need the launch configuration information for all the target devices before the actual launch itself.

We enable MultiCL’s dynamic command queue scheduling by making the following simple code extensions to each benchmark: (1) we set the desired scheduling policy to the context during context creation, and (2) we set individual command queue properties as runtime hints at command queue creation or around explicit code regions. In some kernels, we also use the `clSetKernelWorkGroupInfo` function to separately express the device-specific kernel launch configurations to the runtime, so that the scheduler can have the flexibility to model the kernel for a particular device along with the correct corresponding kernel launch configuration. These simple code changes, together with the MultiCL runtime optimizations, enable the benchmarks to be executed with ideal queue–device mapping. The application developer has to think only about the data-task decompositions among the chosen number of command queues and need not worry about the underlying node architecture.

Table II also shows our chosen MultiCL scheduler options for the different benchmarks. The iterative benchmarks typically have a “warmup” phase during the loop iterations, and we consider them to be ideal candidates for *explicit* kernel profiling because they form the most representative set of commands that will be consistently submitted to the target command queues. For such iterative benchmarks, we set the command queues with the `SCHED_EXPLICIT_REGION` property at creation time and trigger the scheduler explicitly around the warmup code region. We call `clSetCommandQueueSchedProperty` with the `SCHED_AUTO` and `SCHED_OFF` flags to start and stop scheduling, respectively. Other code regions were not considered for explicit profiling and scheduling because they did not form the most representative command set of the benchmark. We also did not choose the *implicit* `SCHED_KERNEL_EPOCH` option for iterative benchmarks because the warmup region spanned across multiple kernel

TABLE II: SNU-NPB-MD benchmarks, their requirements, and our custom scheduler options.

Bench.	Classes	Cmd. Queues	OpenCL Scheduler Option(s)

epochs and the aggregate profile of the region helped generate the ideal queue–device mapping. On the other hand, the EP benchmark (random number generator) is known to be very compute intensive and not iterative. At command queue creation time, we simply set the `SCHED_KERNEL_EPOCH` and `SCHED_COMPUTE_INTENSIVE` properties as runtime hints, which are valid for the queue’s lifetime. In the BT and FT benchmarks, we additionally use our proposed `clSetKernelWorkGroupInfo` OpenCL API (see Section IV) to set CPU- and GPU-specific kernel launch parameters. The parameters that are later passed to `clEnqueueNDRangeKernel` are ignored by the runtime. This approach decouples the kernel launch from a particular device, thus enabling the runtime to dynamically launch kernels on the ideal device with the right device-specific kernel launch configuration.

We evaluate each benchmark with problem sizes from the smallest (S) to the largest problem size that fits on each available device, as specified in Table II. Figure 4 shows a performance comparison of automatic scheduling performed by MultiCL with manual round-robin techniques as the base-

Fig. 4: Performance overview of SNU-NPB-MD for manual and our automatic scheduling. Number of command queues: 4; available devices: 1 CPU and 2 GPUs.

Fig. 5: Distribution of SNU-NPB-MD kernels to devices for manual and MultiCL’s automatic scheduling. Number of command queues: 4; available devices: 1 CPU and 2 GPUs.

line. The benchmark class in the figure denotes the largest problem size for that application that could fit on the device memories, and each benchmark uses four command queues. One can schedule four queues among three devices (2 GPUs and 1 CPU) in  $3^4$  ways, but for our demonstration purpose we showcase a few explicit schedules that we consider are more likely to be explored by users: (1) CPU-only assigns all four command queues to the CPU; (2) GPU-only assigns all four command queues to one of the GPUs; (3) round-robin (GPUs) assigns two queues each to the two GPUs; (4) round-robin #1 assigns two queues to one GPU, one queue to the other GPU, and one queue to the CPU; and (5) round-robin #2 assigns two queues to the CPU and one queue to each GPU. Since five benchmarks perform better on the CPU and EP works best on the GPU, we consider some of the above five schedules to form the best and worst queue–device mappings and expect the MultiCL scheduler to automatically find the best queue–device mapping.

We define the profiling overhead of our scheduler as the difference between the performance obtained from the ideal queue–device mapping and that obtained from the scheduler driven queue–device mapping, expressed as a percentage of the ideal performance, that is,  $\frac{T_{scheduler\_map} - T_{ideal\_map}}{T_{ideal\_map}} * 100$ . Figure 4 shows that automatic scheduling using the MultiCL runtime achieves near-optimal performances, which indirectly means ideal queue–device mapping. The geometric mean of the overall performance overhead is 10.1%. The overhead of FT is more than that of the other benchmarks, and we analyze this overhead in the next paragraph. Figure 5 shows how the performance model in MultiCL’s scheduler has distributed the kernels among the available devices. A close comparison with the benchmarks’ CPU vs. GPU performance from Figure 3 indicates that our scheduler maps queues to devices in a near-ideal manner. For example, Figure 3 indicates that the BT and MG benchmarks perform much better on the CPU than on the GPU, and Figure 5 indicates that our scheduler has assigned most of the kernels from all iterations to the CPU and almost none to the GPU. Similarly, EP performs best on the GPU (Figure 3), and we see that our scheduler has assigned all the kernels to the GPU. The other benchmarks are still better on the CPU but to a lower degree; and thus we see that the CPU

Fig. 6: Profiling (data transfer) overhead for the FT (Class A) benchmark.

Fig. 7: Effect of data caching in reducing profiling overhead for the FT (Class A) benchmark.

still gets a majority of the kernels but that the GPUs also get their share of work. We see similar trends for the other problem classes and other command queue numbers as well, but for brevity we have not included them in the paper.

*Effect of Data Transfer Overhead in Scheduling:* The FT benchmark distributes the input data among the available command queues; that is, the data per queue decreases as the number of queues increases. The MultiCL runtime performs kernel profiling only once per device for performance estimation; hence, the cost is amortized for more command queues, and our profiling overhead reduces. While Figure 4 indicates that the profiling overhead in FT is about 45% when compared with the ideal queue–device mapping and when four command queues are used, Figure 6 indicates that the profiling overhead decreases with increasing command queues. Further, Figure 7 indicates that our data-caching optimization caches the profiled data on the host and reduces the D2D transfer overhead consistently by about 50% during kernel profiling. Although the other benchmarks work on similar data footprints in memory, they do not transfer as much data as FT does, and thus they exhibit apparently negligible data transfer overhead while scheduling.

*Effect of Minikernel Profiling in Scheduling:* The EP benchmark does random number generation on each device

Fig. 8: Impact of minikernel profiling for the EP benchmark.

and is highly compute intensive, and the CPU (nonideal device) can be up to  $20\times$  slower than the GPU (ideal device) for certain problem sizes. Since the full kernel profiling approach runs the entire kernel on each device before device selection, the runtime overhead compared with that of the ideal device combination can also be about  $20\times$ , as shown in Figure 8. Moreover, running the full kernel means that the profiling overhead increases for larger problem sizes. On the other hand, our minikernel profiling approach just runs a single workgroup on each device, and we can see that it incurs a *constant* profiling overhead for any problem size. Minikernel profiling thus dramatically reduces the profiling overhead to only about 3% for large problem sizes, while making optimal device mapping. We perform minikernel profiling for all the other benchmarks as well; but since they are not as compute intensive as EP, the apparent benefits are negligible.

*Summary:* We make parametric changes to at most four OpenCL functions in existing benchmarks and trigger the MultiCL runtime to automatically schedule the command queues and map them to the ideal combination of devices. We choose the autofit global scheduler for the context, while the command queues choose either the explicit region or kernel epoch local scheduler options. The MultiCL scheduler performs static device profiling to collect the device distance metrics, performs dynamic kernel profiling to estimate the kernel running costs, and then computes the aggregate cost metric from the data transfer and kernel execution costs. We derive the data transfer costs based on the device profiles, and the kernel profiles provide the kernel execution costs. We use the aggregate cost metric to compute the ideal queue-device mapping.

2) *Seismology Modeling Simulation:* FDM-Seismology is an application that models the propagation of seismological waves based on the finite-difference method by taking the Earth’s velocity structures and seismic source models as input [22]. The application implements a parallel velocity-stress, staggered-grid finite-difference approach for propagation of waves in a layered medium. In this method, the domain is divided into a three-dimensional grid, and a one-point integration scheme is used for each grid cell. Since the computational domain is truncated in order to keep the computation tractable, absorbing boundary conditions are placed around the region of interest to keep the reflections minimal when boundaries are impinged by the outgoing waves. This strategy helps simulate unbounded domains. The simulation iteratively computes the velocity and stress wavefields within a given subdomain. Moreover, the wavefields are divided into two independent regions, and each region can be computed in parallel. The reference code of this simulation is written in Fortran [23].

For our experiments, we extend an existing OpenCL implementation [24] of the FDM-Seismology simulation as the baseline. The OpenCL implementation divides the kernels into velocity and stress kernels, where each of these sets computes the respective wavefields at its two regions. The velocity wavefields are computed by using 7 OpenCL kernels, 3 of which are used to compute on region-1 and the other 4 kernels

Fig. 9: FDM-Seismology performance overview.

to compute on region-2. Similarly, the stress wavefields are computed by using 25 OpenCL kernels, 11 of which compute on region-1 and 14 kernels compute on region-2. We have two OpenCL implementations of the simulation: (1) *column-major data*, which directly follows Fortran’s column major array structures, and (2) *row-major data*, which uses row major array structures and is more amenable for GPU execution. Moreover, since the two wavefield regions can be computed independently, their corresponding kernels are enqueued to separate command queues. In our experimental system, the two command queues can be scheduled on the three OpenCL devices in  $3^2$  different ways. Figure 9 demonstrates the performance of both versions of the kernels on different device combinations. We see that the column-major version performs best when all the kernels are run on a single CPU and performs worst when all of them are run on a single GPU; the performance difference between the two queue-device mappings is  $2.7\times$ . On the other hand, the row-major version is best when the command queues are distributed across two GPUs and is  $2.3\times$  better than the performance from the worst-case mapping of all kernels on a single CPU.

We compare the performance of two global contextwide schedulers, *round robin* and *autofit*, by simply setting the context property to either the `ROUND_ROBIN` or `AUTO_FIT` values, respectively. FDM-Seismology has regular computation per iteration, and each iteration consists of a single synchronization epoch of kernels. Thus, as our local scheduler, we can either choose the implicit `SCHED_KERNEL_EPOCH` at queue creation time or choose the `SCHED_EXPLICIT_REGION` and turn on automatic scheduling explicitly just for the first iteration by using `clSetCommandQueueSchedProperty`. We use the `SCHED_KERNEL_EPOCH` option in our experiments, but the final mapping and profiling overhead is expected to be the same for the other option as well. Figure 9 shows that the autofit scheduler maps the devices optimally for both code versions. The performance of the autofit case is similar to the CPU-only case for the column-major code and is similar to the dual-GPU case for the row-major version of the code, with a negligible profiling overhead of less than 0.5%. On the other hand, the round-robin scheduler always chooses to split the kernels among the two GPUs and hence does not provide the best combination for the column-order version of the code. Figure 10 shows that for the autofit scheduler, although the first iteration incurs runtime overhead, the added cost gets amortized over the remaining iterations.

Fig. 10: FDM-Seismology performance details. Profiling overhead decreases asymptotically with more iterations.

### C. Programmability Benefits

For all our experiments, we modified about four lines of code in the entire program, on average.<sup>2</sup> The user is required to add new context properties to set the global scheduling policy and set the command queue properties for local policies and runtime scheduler hints. The remaining runtime features are optional, such as using `clSetCommandQueueProperty` to explicitly control the local policy and `clSetKernelWorkGroupInfo` to specify device-specific kernel launch configurations. We have shown that with minimal code changes to a given OpenCL program, our scheduler can automatically map the command queues to the optimal set of devices, thereby significantly enhancing the programmability for a wide range of benchmarks and real-world applications. Our scheduler is shown to incur negligible overhead for our seismology simulation test cases.

## VII. CONCLUSION

We have proposed extensions to the OpenCL specification to control the scheduling both globally at the context level and locally at the command queue level. We have designed and implemented MultiCL, a runtime system that leverages our OpenCL scheduling extensions and performs automatic command queue scheduling capabilities for task-parallel workloads. Our runtime scheduler includes static device profiling, dynamic kernel profiling, and dynamic device mapping. We have designed novel overhead reduction strategies including minikernel profiling, reduced data transfers, and profile data caching. Our experiments on the NPB benchmarks and a real-world seismology simulation (FDM-Seismology) demonstrate that the MultiCL runtime scheduler always maps command queues to the optimal device combination, posing an average runtime overhead of 10% for the NPB benchmarks and negligible overhead for FDM-Seismology application. New OpenCL 2.0 features, such as on-device queues, are worthy of separate in-depth studies and left as future work. Our proposed OpenCL extensions and the associated runtime optimizations enable users to focus on application-level data and task decomposition rather than device-level architectural details and device scheduling.

### ACKNOWLEDGMENT

This material was based upon work supported in part by the U.S. Department of Energy, Office of Science, Advanced Scientific Computing Research (SC-11), under contract DE-AC02-06CH11357, and the VT College of Engineering SCHEV grant. We thank Kaixi Hou for his efforts in porting the seismology simulation code to OpenCL.

<sup>2</sup>We assume that each OpenCL function call can fit in one source line.
