Abstract

We present an initial performance evaluation of the Quadrics interconnection network (QsNET). We describe the main hardware and software features of QsNET of relevance to the system designer and to the end user. Actual benchmarks are performed on an experimental Linux cluster. The preliminary analysis indicates that the interconnect performs remarkably well, e.g., user-level latency and bandwidth of $2.1 \mu\text{s}$ and 200 MB/s, respectively, efficient support for collective communication patterns, and excellent contention resolution under heavy traffic.

Keywords: Interconnection Networks, Performance Evaluation, User-level Communication, Operating System Bypass.

1 Introduction

System interconnection networks have become a critical component of the computing technology, and they are likely to have a great impact on the design, architecture, and use of future high-performance computers. Indeed, not only the sheer computational speed distinguishes high-performance computers from desktop systems, but the efficient integration of the computing nodes into tightly coupled multiprocessor systems. Network adapters, switches, and device driver software are increasingly becoming performance-critical components in modern supercomputers.

A cursory, and admittedly non-comprehensive, look at the state of the art in networking technology in high performance computers indicates a number of notable players. The list includes Gigabit Ethernet [13], Giganet [15], SCI [5], Myrinet [1], GSN (HIPPI 6400)¹, just to name a few.

These network solutions are different in terms of programmability, scalability, topology and performance. At the low end of the performance spectrum we have Gigabit Ethernet which provides a cost-effective solution for system area networks. Giganet, Myrinet and SCI add programmability and performance by using communication processors in the network interface and implementing several types of user-level, operating-system bypass communication protocols.

Infiniband [2] is an evolving standard that provides an integrated approach to high-performance communication by dealing with many aspects of the network architecture, including the elimination of bottlenecks in the I/O bus, programming interface, communication protocols, fault-tolerance, etc.

Some of these salient aspects of Infiniband already exist in the QsNET. In fact, the overall design of the QsNET provides many innovative aspects. These include a novel approach to integrate the local virtual memory into a distributed virtual shared memory, the presence of a programmable processor in the network interface that allows the implementation of intelligent communication protocols, an integrated approach to network fault-detection and fault-tolerance.

¹<http://public.lanl.gov/radiant/research/hippi6400.html>

QsNET is the interconnect adopted by Compaq for its high performance servers. This interconnection strategy is of great importance to the Los Alamos National Laboratory because the 30 TeraOps ASCI² architecture will be centered around it.

This paper presents a performance analysis of the QsNET. Section 2 gives a comprehensive presentation of the two hardware building blocks, the Elan and the Elite. Section 3 discusses the hierarchy of communication libraries. In Section 4 we give a description of our benchmarking methodology and experimental apparatus, while Section 5 presents the experimental results and performance analysis. Some concluding remarks are given in section 6.

2 The QsNET

The QsNET is based on two building blocks, a programmable network interface called Elan [11] and a low-latency high-bandwidth communication switch called Elite [12]. Elites can be interconnected in a fat-tree topology [6]. The network has several layers of communication libraries which provide trade-offs between performance and ease of use. Other important features are hardware support for collective communication patterns and fault-tolerance.

2.1 Elan

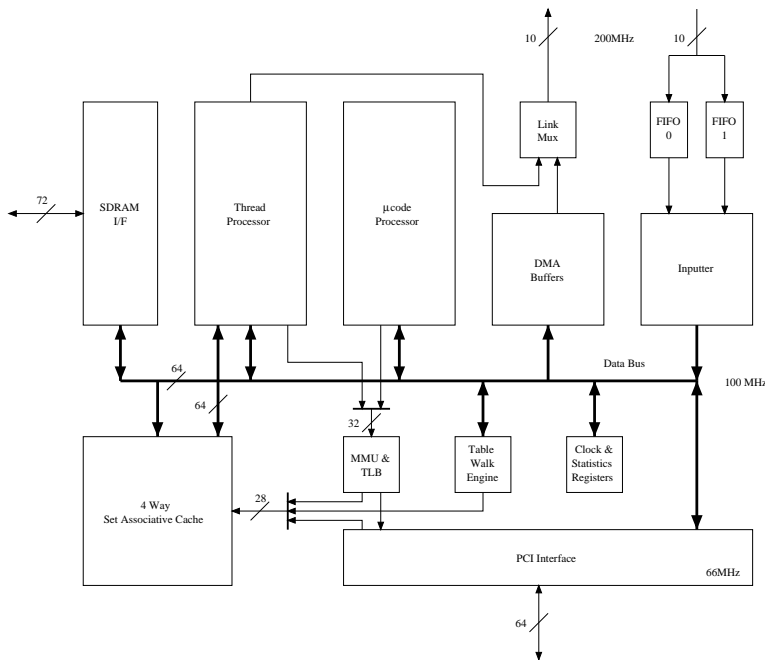

Figure 1: Elan Functional Units

The Elan³ communications processor links the high-performance, multi-stage Quadrics network to a processing node containing one or more CPUs. In addition to generating and accepting packets to and from the network, the Elan also provides substantial local processing power to implement high-level message-passing protocols such as MPI. The internal functional structure of the Elan, shown in Figure 1, centers around two primary processing engines: the microcode processor and the thread processor.

The 32-bit microcode processor supports four separate threads of execution, where each thread can independently issue pipelined memory requests to the memory system. Up to eight requests can be outstanding

²http://www5.compaq.com/alphaserver/news/supercomputer_0822.html

³This paper refers to the Elan3 version of the Elan. We will use Elan and Elan3 interchangeably throughout the paper.

at any given time. The scheduling for the microcode processor is extraordinarily lightweight, enabling a thread to wake up, schedule a new memory access on the result of a previous memory access, and then go back to sleep in as few as two system-clock cycles.

The four microcode threads are described below: (1) *inputter thread*: Handles input transactions from the network. (2) *DMA thread*: Generates DMA packets to be written to the network, prioritizes outstanding DMAs, and time-slices large DMAs so that small DMAs are not adversely blocked. (3) *processor-scheduling thread*: Prioritizes and controls the scheduling and descheduling of the thread processor. (4) *command-processor thread*: Handles operations requested by the host (i.e., “command”) processor at user level.

The thread processor is a 32-bit SPARC-based RISC processor used to aid the implementation of higher-level messaging libraries without explicit intervention from the main CPU. In order to better support the implementation of high-level message-passing libraries without explicit intervention by the main CPU, the thread processor’s instruction set was augmented with extra instructions that construct network packets, manipulate events, efficiently schedule threads, and block save and restore a thread’s state when scheduling.

The MMU translates 32-bit virtual addresses into either 28-bit local SDRAM physical addresses or 48-bit PCI physical addresses. To translate these addresses, the MMU contains a 16-entry, fully-associative, translation lookaside buffer (TLB) and a small data-path and state machine used to perform table walks to fill the TLB and save trap information when the MMU faults.

The Elan contains routing tables that translate every virtual processor number into a sequence of tags that determine the network route. Several routing tables can be loaded in order to have different routing strategies.

The Elan has 8KB of cache memory, organized as 4 sets of 2KB and 64MB of SDRAM memory. The cache line size is 32 bytes. The cache performs pipelined fills from the SDRAM and is able to issue a number of cache fills and write backs for different units while still being able to service accesses for units that hit on the cache. The interface to the SDRAM has 64 bits and there are 8 check bits added to provide Error Code Correction. The memory interface also contains a 32 byte write buffer and a 32 byte read buffer.

The link logic transmits and receives data from the network and outputs 9 bits and a clock signal on each half of the clock cycle, Each link provides buffer space for two virtual channels with a 128 entry, 16 bit FIFO RAM for flow control.

2.2 Elite

The other building block of the QsNET is the Elite switch. The Elite provides the following features: (1) 8 bidirectional links supporting two virtual channels in each direction, (2) an internal 16×8 full crossbar switch⁴, (3) a nominal transmission bandwidth of 400 MB/s on each link direction and a flow through latency of 35 ns, (4) packet error detection and recovery, with routing and data transactions CRC protected, (5) two priority levels combined with an aging mechanism to ensure a fair delivery of packets in the same priority level, (6) hardware support for broadcasts, (7) and adaptive routing.

The Elite switches are interconnected in a quaternary fat-tree topology, which belongs to the more general class of the k -ary n -trees [8] [7]. A quaternary fat-tree of dimension n is composed of 4^n processing nodes and $n * 4^{n-1}$ switches interconnected as a delta network, and can be recursively build by connecting 4 quaternary fat trees of dimension $n - 1$.

Quaternary fat trees of dimension 1, 2 and 3 are shown in Figure 2.

Elite networks are source routed. The route information is attached to the packet header before injecting the packet into the network and is composed by a sequence of Elite link tags. As the the packet moves inside the network, each Elite removes the first route tag from the header, and forwards the packet to the next Elite in the route or to the final destination. The routing tag can identify either a single output link or a group of links.

The transmission of each packet is pipelined into the network using wormhole flow control. At link level, each packet is partitioned in flits (flow control digits) [3] of 16 bits. Every packet is closed by and End Of

⁴The crossbar has two input ports for each input link, to accommodate the two virtual channels.

Figure 2: 4-ary n -trees of dimension 1, 2 and 3.

Packet (EOP) token, but this is normally only sent after receipt of a packet acknowledge token. This implies that every packet transmission creates a virtual circuit between source and destination.

Packets can be sent to multiple destinations using the broadcast capability of the Elan network. For a broadcast packet to be successfully delivered a positive acknowledgement must be received from all the recipients of the broadcast group. All Elans connected to the network are capable of receiving the broadcast packet but, if desired, the broadcast set can be limited to a subset of physically contiguous Elans.

3 Programming libraries

The Elan network interface can be programmed using several programming libraries [10], as outlined in Figure 3. These libraries trade speed with machine independence and programmability. Starting from the bottom, Elan3lib is the lowest programming level available in user space which allows the access to the low level features of the Elan3. At this level, processes in a parallel job can communicate with each other through an abstraction of distributed virtual shared memory. Each process in a parallel job is allocated a virtual process id (VPID) and can map a portion of its address space into the Elan. These address spaces, taken in combination, constitute a distributed virtual shared memory. Remote memory (i.e., memory on another processing node) can be addressed by a combination of a VPID and a virtual address. Since the Elan has its own MMU, a process can select which part of its address space should be visible across the network, determine specific access rights (e.g. write- or read-only) and select the set of potential communication partners.

Elanlib is a higher level layer that frees the programmer from the revision-dependent details of the Elan, and extends Elan3lib with point-to-point, tagged message passing primitives (called Tagged Message Ports or Tports). Standard communication libraries as such MPI-II [4] or Cray Shmem are implemented on top of Elanlib.

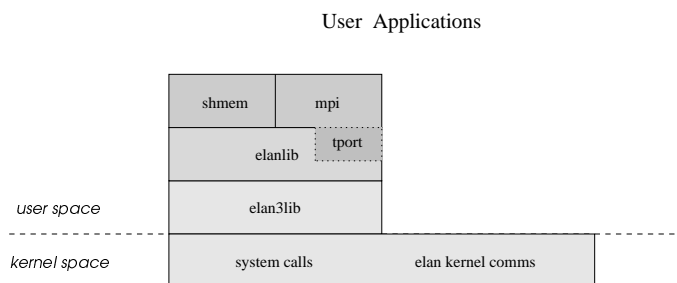

Figure 3: Elan3 programming library hierarchy

3.1 Elan3lib

The Elan3lib library supports a programming environment where groups of cooperating processes can transfer data directly, while protecting process groups from each other in hardware. The communication takes place at user level, with no copy, bypassing the operating system. More information on Elan3lib is provided in Appendix A

3.2 Elanlib and Tports

Elanlib is a machine independent library that integrates the main features of Elan3lib with the Tports. Tports provide basic mechanisms for point-to-point message passing. Senders can label each message with a tag, the sender identity and the size of the message. This is known as the *envelope*. Receivers can receive their messages selectively, filtering them according to the identity of the sender and/or a tag on the envelope. It is worth noting that the Tports programming interface is very similar to MPI [14].

4 Experimental Framework

We tested the main features of the QsNET on an experimental cluster with 8 dual-processor SMPs equipped with 733MHz Pentium III. Each SMP uses a motherboard based on the 840 Intel chipset with 512MB of SDRAM. The motherboard provides two 64 bits/66Mhz PCI slots and one of them is used by the Elan3 PCI card QM-400. The interconnection network is a quaternary fat-tree of dimension two, as the one shown in Figure 2 b), with 16 external ports, the QM-S16, composed of 8 8-port Elite switches integrated in the same board. The operating system used during the evaluation is Linux 2.3.99.

The preliminary results shown in this paper try to expose basic performance of the interconnection network. For this reason, most of the benchmarks are written at Elan3lib level. We will also shortly analyze the overhead introduced by Elanlib and MPI. A list of performed experiments follows.

4.1 Unidirectional Ping

We analyze the latency and the bandwidth of the network by sending messages of increasing size from a source to a destination SMP. In order to identify different bottlenecks, the communication buffers are placed either in main or in Elan memory. The alternatives include main memory to main memory, Elan memory to Elan memory, Elan memory to main memory and main memory to Elan memory. These buffers are placed in the desired type of memory using the allocation mechanisms provided by Elan3lib, as described in Section 3.1.

For the unidirectional ping we report graphs showing latency and bandwidth. The latency is measured as the elapsed time between the posting of the remote DMA request and notification of the successful completion at the source (steps 2 through 10 in Figure 11). As a consequence, the results shown in the experimental evaluation are slightly conservative for small messages. The unidirectional ping tests for the Tports and MPI are implemented using matching pairs of blocking sends and receives.

4.2 Bidirectional Ping

The unidirectional ping experiments can be considered as the “peak performance” of the network. By sending packets in both directions along the same network path we can expose several types of bottlenecks.

For example, the Elan microcode interleaves four activities, DMA engine, inputter, command processor and thread processor. This test can evaluate how the DMA engine and the inputter can work with bidirectional traffic. Also the link-level flow control requires the transmission of control information, which can lead to a degradation of the unidirectional performance in the presence of bidirectional traffic.

4.3 Hotspot

A further test of the network and the network interface is the hotspot. Under hotspot traffic, a set of communication partners try to read from or write into the same memory block. This localized communication pattern can lead to a severe form of congestion a know as *tree saturation* [9], which can seriously degrade the performance of the overall network. In our experiments we will consider both *read* and *write* hotspots.

5 Experimental Results

5.1 Unidirectional Ping

Figure 4 compares the performance of the unidirectional ping for the three communication libraries. The lowest values of approximately 200 MB/s for the bandwidth (the lowest two overlapped curves) are MPI and the Tports when the buffers are allocated in the main memory. At Elan3lib and Tports level, when the source and destination buffers are allocated in the Elan memory, we note a significant bandwidth increase in all message size ranges, as expected. The saturation value of the bandwidth in this case increases from 200 MB/s to 335 MB/s. The intermediate value of 275 MB/s is obtained when the source buffer is in the Elan and the destination buffer is in main memory. An interesting observation from these measurements comes from noting that the 6 plots in the figure are grouped in 3 sets of two with identical saturation values.

The peak bandwidth of 335 MB/s is reached when both source and destination buffers are placed in the Elan memory. The maximum packet size that can be sent by the current Elan implementation is 320 bytes of data payload. This is partitioned in five low-level write-block transactions of 64 bytes. For this message format, the overhead is 58 bytes, for the message header, CRCs, routing info, etc. This implies that the peak bandwidth delivered by the network is approximately 396 MB/s, or 99% of the nominal bandwidth of 400 MB/s.

Another important characteristic is the asymmetry in performance between the main-to-Elan and Elan-to-main mappings. This is somewhat counterintuitive, but it can be explained by an asymmetry in the PCI bus, allowing larger bandwidth for operations incoming into the Elan. The achieved burst write performance for the PCI bus is 275 MB/s while the burst read is only 200 MB/s.

The overlap between the bandwidth in the main-to-Elan and main-to-main experiments indicates that the bottleneck is in the PCI bus, for outgoing memory operations. For all buffer mapping strategies, $N^{1/2}$ is approximately 512 bytes.

Figure 5 shows the latency in the range $[0 \dots 1KB]$. With Elan3lib the basic latency for 0-byte messages is only 2.1 μs and is constant for messages up to 64 bytes, because these messages can be packed as a single write-block transaction. When both source and destination buffers are in the Elan, the network can deliver up to 64 bytes in 2.4 μs . Main memory to main memory transfers require 3.7 μs in the same message range. Again, memory reads issued over the PCI bus are slower then memory writes. The slight increase for 1-byte messages is due to some extra overhead to extract the single byte from the incoming message and deal with misalignment problems.

We note an increase in the latency at the Tports and MPI level, compared to the latency at the Elan3lib level, from approximately 3 μs to 5 μs . The extra cost is due to the overhead of tag matching, meaning that from the Elan3lib level, in which latency is mostly hardware, system software is needed to run as a thread in the Elan microprocessor in order to match the message tags. This introduces the extra overhead responsible

for the higher latency value. The noisy upper 2 curves are the latency measurements for Tports when the source is mapped into the Elan. Currently we have no explanation for the performance glitch shown in this measurement.

5.2 Bidirectional Ping

In this benchmark, whose results are shown in Figure 6, we continue to draw the curves corresponding to the experiments described in the previous case. The first overall observation is that, whereas the curves in Figure 4 are very smooth, the ones in this case exhibit some fluctuations. We see that the claimed bidirectionality of the network is not fully achievable. The maximum unidirectional value, obtained as 1/2 of the measured bidirectional traffic, with both communication buffers mapped on the Elan is about 270 MB/s, whereas in the previous case it was 335 MB/s. This difference in the Elan-to-Elan bandwidth identifies potential bottlenecks in the network or the network interface, as opposed to the PCI bus. Potential causes of this performance degradation can be the interleaving of the DMA engine with the inputter, the sharing of the internal data bus of the Elan and also interferences at link level in the Elite network. We plan to further investigate these problems using the performance counters available on the Elan.

The bidirectional bandwidth for the main memory to main memory traffic is 140 MB/s for both Elan3lib and Tports.

We note (Figure 7) that the latency increase for small messages is about 1/2 μ s: from 2.3 μ s to 2.8 μ s for Elan-to-Elan communication and from 3.6 μ s to 4.1 for main memory to main memory.

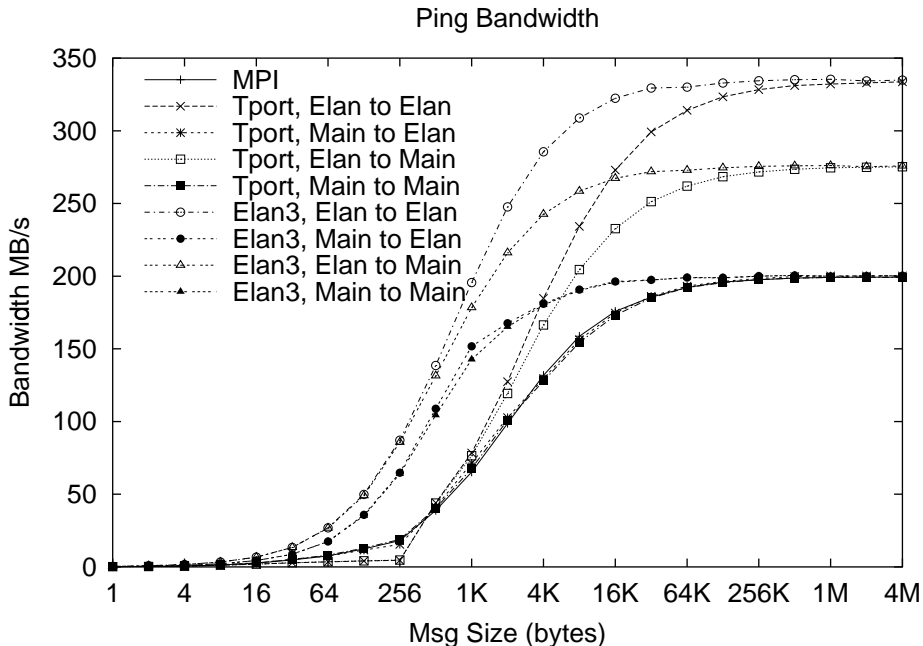

Figure 4: Unidirectional Ping Bandwidth

5.3 Read Hotspot

In this experiment we attempt to read the same memory location from an increasing number of processors (one per SMP). The bandwidth plot is depicted in Figure 8. The upper (constant) curve is the aggregate bandwidth of all processes. The curve is remarkably flat, to a constant value of 200 MB/s, exactly the value in Figure 4 for the main memory to main memory curve. The lower curve is the per-process bandwidth. The scalability of this type of memory operation is very good, up to the available number of processors in

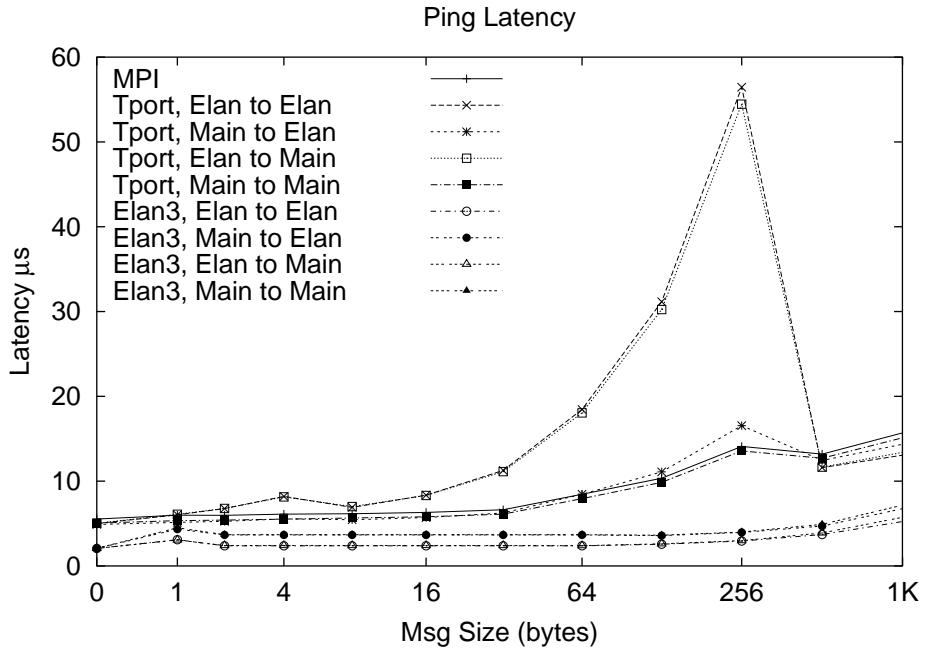

Figure 5: Unidirectional Ping Latency

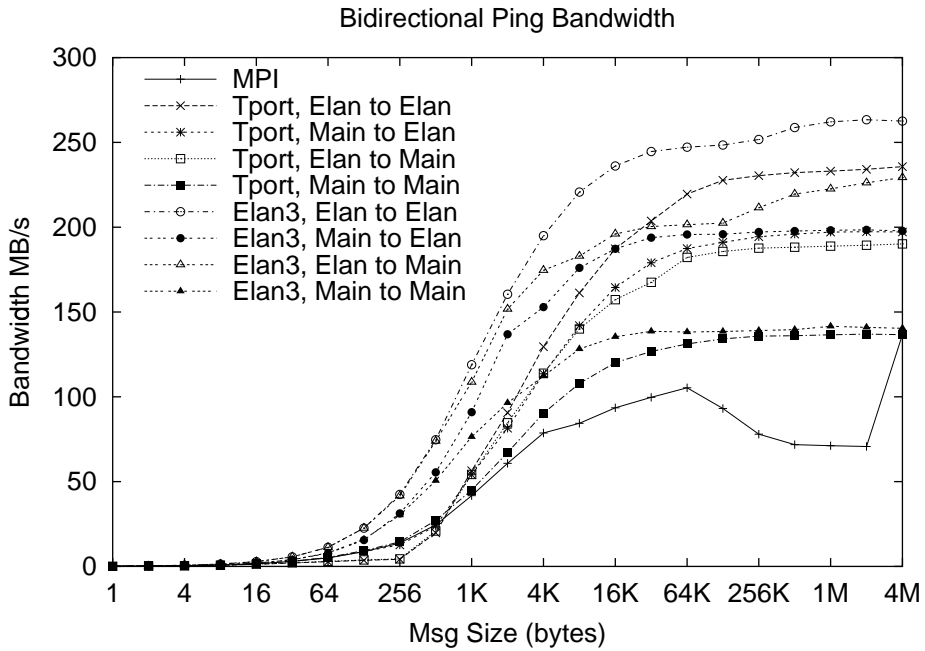

Figure 6: Bidirectional Ping Bandwidth

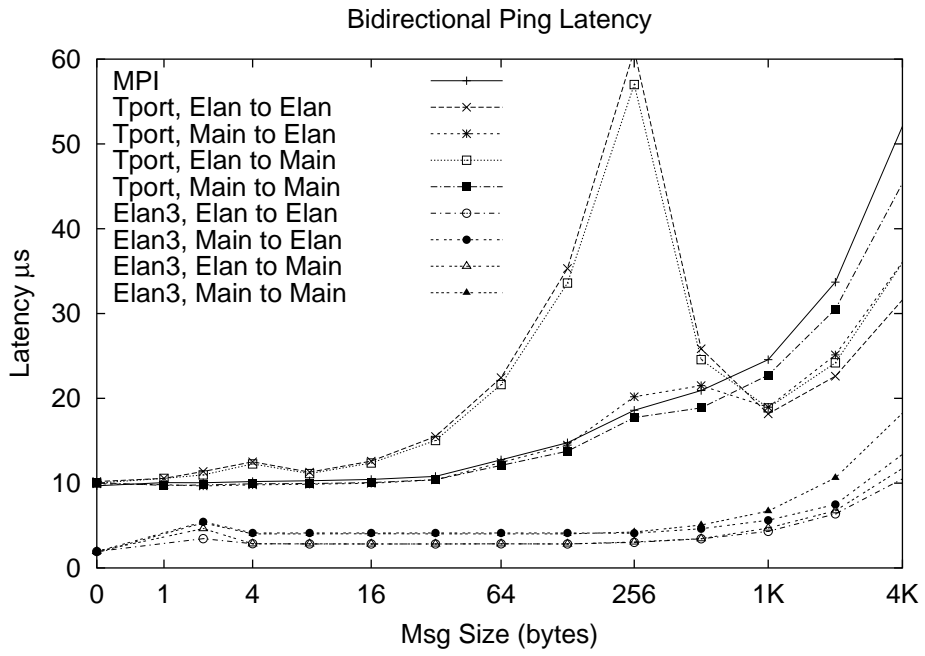

Figure 7: Bidirectional Ping Latency

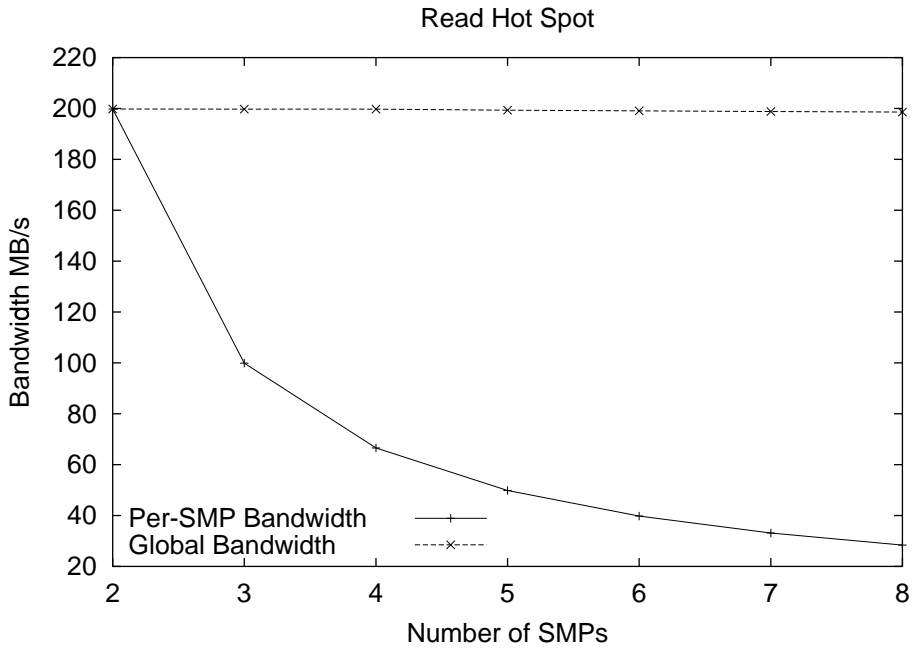

Figure 8: Read Hotspot

our cluster. Hot-spot operations, both on read and on write, are very common in scientific computing, hence the scalability of hotspot resolution is very important.

5.4 Write Hotspot

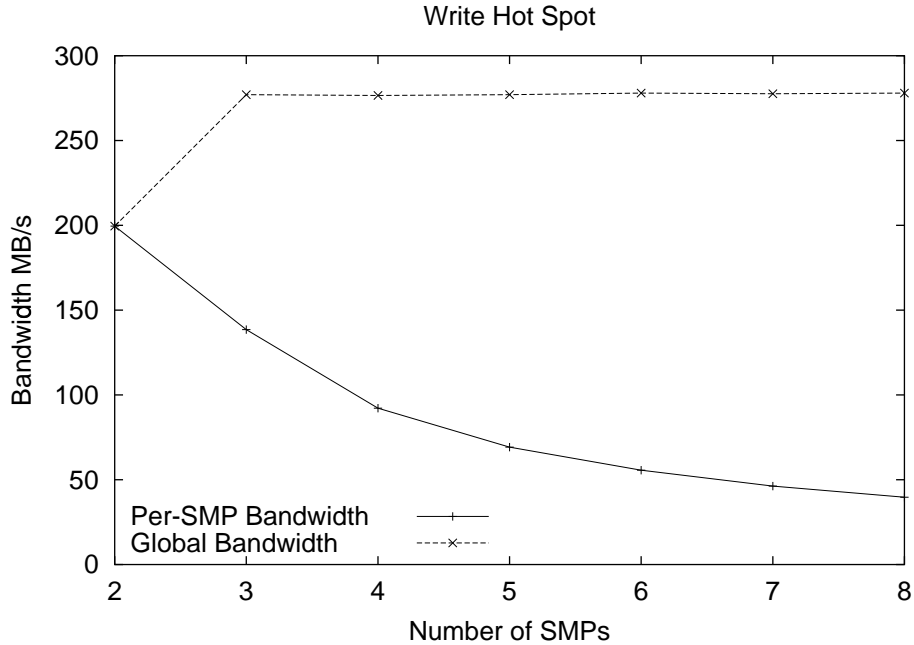

Figure 9: Write Hotspot

The two curves depicted in figure 9 are the same as those in Figure 8, only for writes. The global bandwidth on writes is pretty constant to a value of 275 MB/s, the upper bound determined by the PCI bus for the burst write. The initial jump in bandwidth when going from 2 to more processors is due to the fact that on the sending side, only 200 MB/s can be achieved. On the receiving side, as seen from figure 4, 275 MB/s are achievable.

6 Conclusion and Future Work

We presented the results of several performance tests on the QsNET targeting essential performance characteristics. At the lowest level of the communication hierarchy, the unidirectional latency is as low 2.1 μ s and the bandwidth as high as 200 MB/s. These performance numbers are influenced by the mapping of the buffers in various levels of the memory hierarchy. The network bandwidth, measured by placing the communication buffers in the Elan memory is about 335 MB/s. Bidirectional measurements indicate a degradation in performance which is analyzed and explained in the paper. At higher levels in the communication hierarchy, Tports still exhibit excellent performance figures comparable to the ones at Elan3lib level. The current MPI implementation shows some performance degradation under contention. In summary, our analysis shows that in all the components of the performance space we analyzed, the network delivers adequate performance levels to the end user. The glitches that we uncovered are likely to be fixed by the network designers in the near future.

Future work includes scalability analysis for larger configurations, performance of a larger subset of collective communication patterns and performance analysis of ASCI applications.

A Elan3lib

The main features of Elan3lib are: (1) event notification, (2) the memory mapping and allocation scheme and (3) remote DMA transfers.

A.0.1 Event Notification

Events provide a general purpose mechanism for processes to synchronize their actions. The mechanism can be used by threads running on the Elan and processes running on the main processor. Events can be accessed both locally and remotely. In this way, processes can be synchronized across the network, and can be used to indicate the end of a communication operation, such as a completion of a remote DMA. Events are stored in Elan memory, in order to guarantee the atomic execution of the synchronization primitives⁵. Processes can wait for an event to be triggered by blocking, busy waiting or polling. In addition, an event can be tagged as being a block copy event. The block copy mechanism works as follows. A block of data in Elan memory is initialized to hold a pre-defined value. An equivalent sized block is located in main memory, and both are in the user's virtual address space. When the specified event is set, for example when a DMA transfer has completed, a block copy takes place. That is, the block in Elan memory is copied to the block in main memory. The user process polls the block in main memory to check its value, (for example, bringing a copy of the corresponding memory block into the L2 cache) without having to poll for this information across the PCI bus. When the value is the same as that initialized in the source block, the process knows that the specified event has happened.

A.0.2 Memory Mapping and Allocation

The MMU in the Elan can translate between virtual addresses written in the format of the main processor (for example, a 64-bit word, big Endian architecture as the AlphaServer) and virtual addresses written in the Elan format (a 32-bit word, little Endian architecture). For a processor with a 32 bit architecture (for example an Intel Pentium), a one-to-one mapping is all that is required.

In Figure 10 the mapping for a 64-bit processor is shown. The 64 bit addresses starting at 0x1FF0C808000 are mapped to Elan's 32 bit addresses starting at 0xC808000. This means that virtual addresses in the range 0x1FF0C808000 to 0x1FFFFFFFFFFFF can be accessed directly by the main processor while the Elan can access the same memory by using addresses in the range 0xC808000 to 0xFFFFFFFF. In our example, the user may allocate main memory using malloc and the process heap may grow outside the region directly accessible by the Elan delimited by 0x1FFFFFFFFFFFF. In order to avoid this problem, both main and Elan memory can be allocated using a consistent memory allocation mechanism. As shown in Figure 10 the MMU tables can be set up to map a common region of virtual memory called *memory allocator heap*. The allocator maps physical pages, of either main memory or Elan into this virtual address range on demand. Thus, using allocation functions provided by the Elan library, portions of virtual memory (1) can be allocated either from main or Elan memory, and (2) the MMUs of both main processor and Elan can be kept consistent.

For reasons of efficiency, some objects can be located on the Elan, for example communication buffers or DMA descriptors which the Elan can process independently of the main processor.

A.0.3 Remote DMA

The Elan supports remote DMA (Direct Memory Access) transfers across the network, without any copying or buffering or operating system intervention. The process that initiates the DMA fills out a DMA descriptor, which is typically allocated on the Elan memory for efficiency reasons. The DMA descriptor contains the VPIDs of both source and destination, the amount of data, the source and destination addresses, two event locations (one for the source and the other for the destination process) and other information used to enhance fault tolerance.

The typical steps of remote DMA are outlined in Figure 11.

⁵The current PCI bus implementations cannot guarantee atomic execution, so it is not possible to store events in main memory.

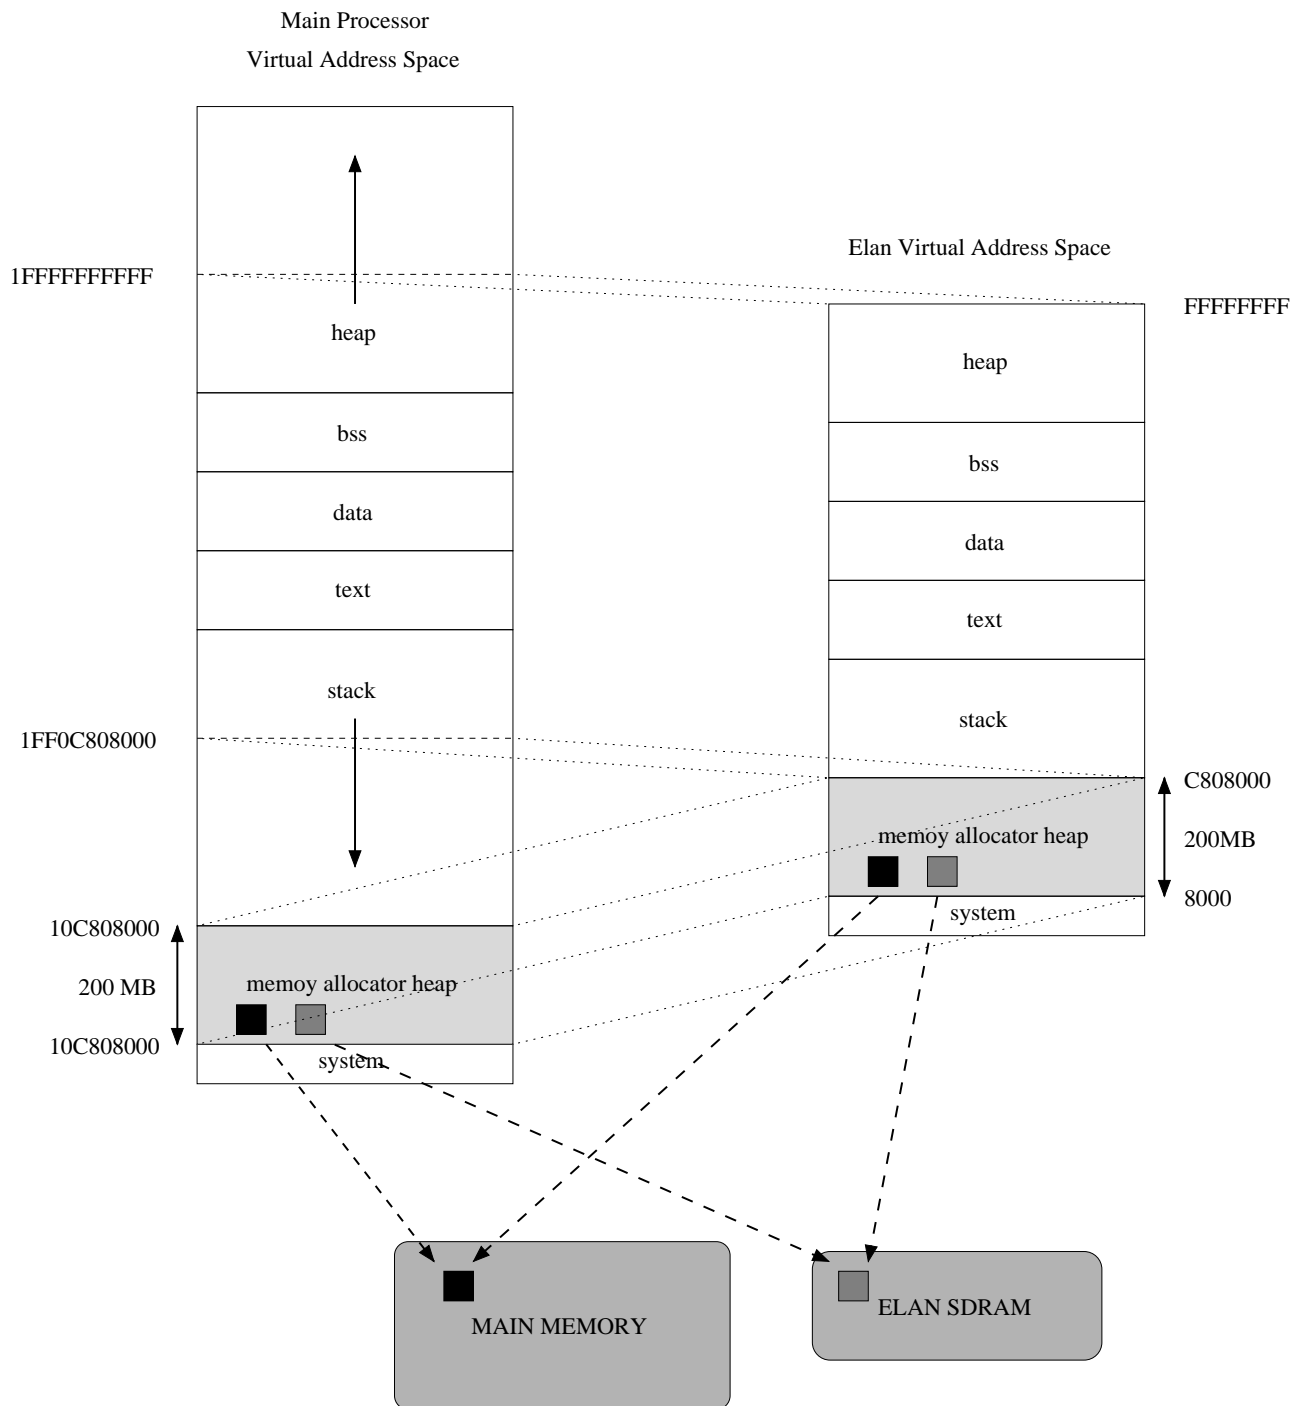

Figure 10: Virtual Address Translation

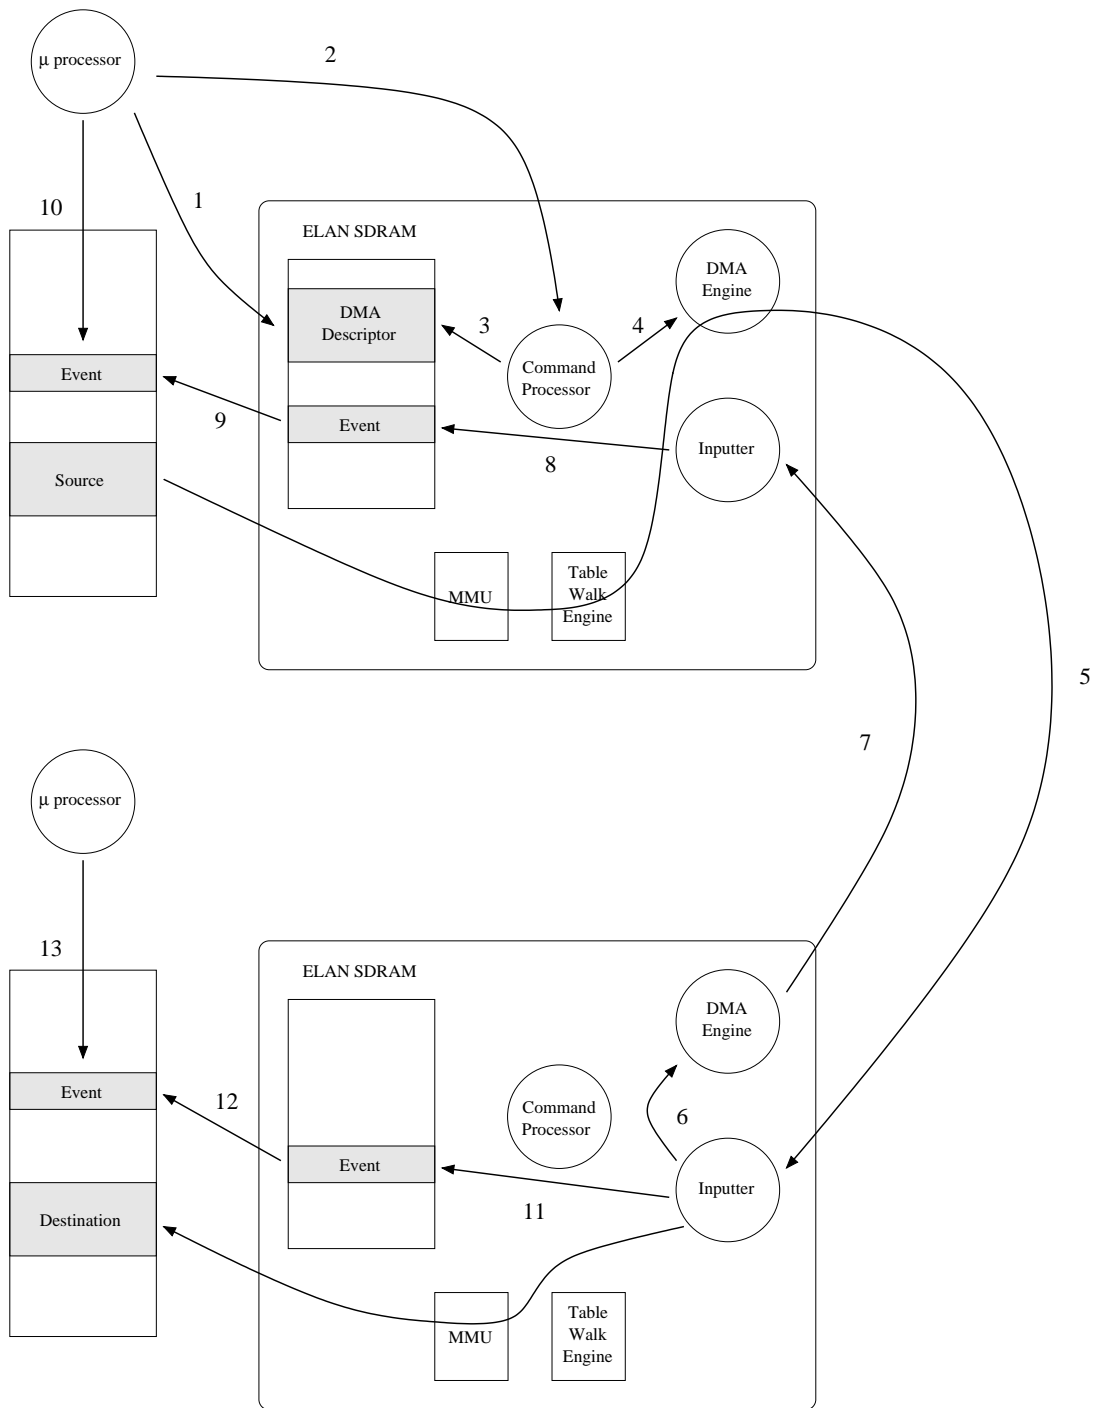

Figure 11: Execution of a Remote DMA. The sending process (1) initializes the DMA descriptor in the Elan memory and (2) communicates the address of the DMA descriptor to the command processor. The command processor (3) checks the correctness of the DMA descriptor and (4) adds it to the DMA queue. The DMA engine (5) performs the remote DMA transaction. Upon completion the remote inputter (6) notifies the DMA engine which (7) sends an ack to the source Elan. Source (8-10) and destination (11-13) events can be notified, if needed.
